Abstract— Cloud computing brings flexible and cost-effective services. However, security concerns plague the cloud. Data confidentiality is one of the security concerns inhibiting the adoption of cloud computing. This concern stems from various cyberattacks directed towards gaining unauthorised access to cloud-bound or cloud-hosted data. This paper proposes a client-end encryption and key management system to curb cyberattacks that target compromising data confidentiality on the cloud. The proposed system uses chaotic atmospheric noise to generate a fitness function. The fitness function is used to generate random numbers, which are used to create encryption keys. The strength of the encryption keys is derived from the chaotic and random nature of the atmospheric noise. The keys are then used for encrypting cloud-bound data using Advanced Encryption Standard (AES- 128, 192 and 256), Data Encryption Standard (DES), 3-DES, and our novel cryptosystem named Cryptor, before it can be sent to the cloud. However, encryption bears no significance if the key management system is flawed. To address the inherent key management problem, the solution uses a neural network to learn patterns of an encryption key. Once learnt, the key is discarded to thwart possible key attacks. The key is reconstructed by the neural network for decryption purposes.

Keywords— Cloud computing, confidentiality, chaotic noise, encryption, neural network.

I. INTRODUCTION

Cloud computing has gained considerable popularity. This is due to the exponential increase in the use of the Internet-based services e.g. software as a service (SaaS), platform as a service (PaaS), infrastructure as a service (IaaS). Cloud computing brings attractive benefits. For example, resource sharing, storage capacities, pay-per-use model etc. However, despite having such advantages, the cloud is afflicted with security concerns. Among the concerns is data confidentiality breaches.

Quite often, information security practitioners make use of encryption systems to achieve data confidentiality guarantees. Several encryption systems are used to secure cloud services. For example, Data Encryption Standard (DES), its variant triple DES, Advanced Encryption Standard (AES), the Rivest, Adleman and Shamir (RSA) algorithm and others. However, cybercriminals are continually finding new ways of

compromising the confidentiality of cloud-hosted data and services. Cybercriminals continue to develop new tools, techniques and procedures (TTPs) to breach existing encryption systems and steal cloud-hosted data. Hence, the adoption of cloud-based services hinges on getting right the issues that relate to data confidentiality [1]. Data confidentiality issues mainly arise from the fact that cloud-based services can be accessed from virtually anywhere, at any time, using any Internet-enabled device. Such convenience in terms of accessibility opens gaping vulnerabilities that get exploited by various attacks that target compromising the confidentiality of cloud-hosted data. For example, inter-VM, VM-sprawl and insider attacks exploit vulnerabilities in virtual machines and hypervisors to breach the confidentiality of cloud-hosted data. Existing cryptographic solutions are proving to be insufficient in dealing with these new threats. This has created a need for better mechanisms to deal with the new threats that are specific to the cloud. Therefore, new encryption systems are required to provide data confidentiality guarantees and to thwart recurring and new cyber-attacks.

Moreover, due to the emergence of various digital devices such as smart phones, tablets, laptops etc., enormous amounts of digital content are generated and sent for storage on the cloud. Cloud service providers (CSPs) such as Google, Dropbox, Microsoft, Apple, Amazon etc., offer individuals, small and big organizations cloud storage services to store their data. This service comes at a fraction of the cost of hosting the data in-house. Thus, the cloud is bulging with digital content. The digital content explosion is envisaged to increase exponentially in years to come. The increasing use of cloud storage services to store digital content calls for secure encryption measures to provide strong confidentiality guarantees on the data. Therefore, some CSPs already provide encryption mechanisms to ensure secure storage services that guarantee confidentiality to cloud-hosted data. For example, Dropbox uses AES-256 and a transport layer security (TLS) protocol to provide data confidentiality for its customers [2]. Despite the efforts of some CSPs in trying to implement strong encryption to protect cloud-hosted data from any malicious attacks, there have been numerous security breaches that have resulted in confidential data leakages. For example, the same

Dropbox which uses AES-256 has experienced a cyber-attack in which user credentials were stolen and used to reveal customers' cloud-hosted data [3].

Furthermore, some CSPs are bound by service level agreements (SLAs), regulatory compliance and legal policies to provide confidentiality guarantees on cloud-hosted data [4]. Despite such legal and regulatory policy enforcement, data leakage breaches are widespread and come with huge consequences. Surely, there is something wrong with the current approaches. It appears that most encryption systems are implemented on the CSP's end which indicates that the resultant encryption keys are also managed by the CSP or a third party. However, some CSPs have moved towards encrypting customers' cloud-hosted data and hand the keys back to the customers (i.e. the keys to the data are not on the CSPs premises). Some CSPs have involved third parties to manage encryption keys. All these approaches have been tried and tested. However, it must be noted that weak encryption or a flawed key management system often results in confidential data leakages which have severe financial implications to the customer and the breached CSP. Thus, encryption on the cloud requires careful attention and must be perfected to provide the right levels of confidentiality guarantees to cloud-hosted data.

Therefore, this paper addresses data confidentiality issues on the cloud from the perspective of strong encryption and secure key management. The remainder of this paper is structured as follows: section II discusses existing literature. Section III introduces the proposed model. Section IV presents and discusses the results of the proposed solution. Section V concludes the paper and provides future recommendations.

II. LITERATURE REVIEW

Various research related to cloud encryption has been conducted. In the quest to achieve data confidentiality, encryption is cited as the widely-used method [5][6].

Neural cryptography is a new technique for providing data confidentiality [7]. This technique combines the concepts of machine learning and cryptography, using neural networks (NNs). Artificial intelligence techniques are proposed to invent cryptosystems to curb eavesdropping. This research [7] proposes two artificial neural networks for develop a cryptographic algorithm to protect data. The encryption part was a success as the neural networks successfully communicated securely, avoiding eavesdropping. However, the solution requires large memory due to the exponential growth of the type of NNs used. It also takes longer periods to exchange a secret key between the two communicating neural networks. These issues make the solution inefficient.

A neural cryptographic scheme is proposed in [8]. This scheme is based on mutual machine learning concepts. The idea of mutual machine learning is gaining popularity in various aspects of neural cryptography. For example, using synchronization, the prevalent key distribution problems faced by most encryption systems might be solved. The proposed scheme uses two feed-forward neural networks. The NNs have discrete and continuous weights. The proposed scheme encrypts data successfully. However, this solution is susceptible to genetic, geometric and probabilistic attacks [9]. Using genetic algorithms, the scheme can be easily defeated by mutating a fitness function until a matching encryption key is found. This is analogous to a brute-force attack.

Another study proposes a neural cryptographic scheme using information substitution and permutations [9]. These two techniques are meant to achieve confusion and diffusion when encrypting data. This scheme uses a recursive, modulo-2 substitution and two feed-forward NNs. Communicating NNs receive a unique input vector to produce a unique output bit. This process is repeated a number of times to generate a secret key. This scheme encrypts plaintext through a recursive modulo-2 substitution phase to produce ciphertext. This ciphertext is then enciphered to produce the final ciphertext, using a cipher block chain (CBC) and an exclusive OR (i.e. *XOR*) operation. The CBC and *XOR* operations are applied on vectors with identical weights and intermediate ciphertext block lengths. As with most neural network implementations, neural cryptographic schemes require large memory as the feed-forward neural networks grow exponentially and require huge amounts of training time.

Homomorphic encryption is one of the methods proposed for ensuring data confidentiality. The notion of homomorphic encryption was introduced by Rivest, Adleman and Dertouzos [10]. Homomorphic encryption is based on the ability to perform certain computations, such as addition and multiplication on ciphertext, without using a decryption key to decrypt the data. This allows third parties such as CSPs, to perform limited queries on ciphertext while preserving the confidentiality of the data. However, homomorphic encryption schemes have vulnerabilities and can be broken [11]. It has been proven that deterministic homomorphic ciphers can be broken in sub-exponential time [12]. This becomes worse in a quantum computing space. A study showed that homomorphic schemes with deterministic properties can be broken using quantum computations [13]. Furthermore, existing schemes are not fully homomorphic as they allow only one operation, either addition or multiplication, on a ciphertext. Fully homomorphic encryption schemes have been proposed to allow both operations on ciphertext [14]. However, fully homomorphic encryption schemes are slow, resource intensive and have not been tested for practical implementations.

Studies on encryption, key management and data confidentiality on the cloud have been conducted before. A client-end cryptosystem for encrypting data prior to uploading it to the cloud is proposed [15][16]. Although the cryptosystem achieves data confidentiality, its major downfall is on the key management system. The authors propose to blend the encryption key with the ciphertext. This becomes security by obscurity - a vulnerability as cybercriminals might find out that the key is part of the ciphertext. Hence, the confidentiality of the data will be compromised.

A light-weight AES-128, a secure hash algorithm (SHA-512) and water-marking are security mechanisms proposed to provide confidentiality of cloud-hosted data in [17]. This study also uses the Bell & Lapadula model for authorization purposes. The authors implement a real-time identification scheme to curb data leaks through a cache technique. The technique they implement uses a VM cache memory to identify authenticated and authorized users. The contents of the VM cache memory are encrypted with AES-128 and sent to an authentication server. The authentication server decrypts the message header to find the user credentials. However, virtual cache memory may not uniquely identify cached data due to aliasing. Aliasing means that a virtual memory address may be mapped to a

different physical memory address. Hence, virtual cache memory is susceptible to end channel attacks [18]. The authors show how a novel attack vector can easily exploit vulnerabilities of the hypervisor and other software security monitors. The attack vector uses aliasing to place incoherent copies of physical addresses on a cache memory. Thus, virtual indexing is a one-to-many function. Such functions may not be desirable where unique identifiers are used, such as in a cloud environment. Hence, an unauthorized user might gain access to confidential data.

An approach combining encryption and data fragmentation is proposed has been proposed [19]. Fragmentation ensures that data is split into several fragments which can be stored in distributed cloud databases provided by CSPs. Fragmentation may be implemented either vertically or horizontally across a relational database to store data in various data centers. This is also very useful for backup purposes. However, efficiency in data retrieval may be an expensive process especially if one of the sites (i.e. database storing fragments) is inaccessible due to network problems as the fragments will not be enough to reconstruct the data.

To ensure confidentiality guarantees, this study advocates for client-end encryption. This approach aims to avoid confidential data leaks due to intentional or accidental incidents. CSPs may also be compelled to provide “back doors” for law enforcement agencies to have uninterrupted access and surveillance of cloud-hosted data. For example, the widely-reported case between the Federal Bureau of Investigation (FBI) and Apple, the Microsoft court case on stored emails etc., have set new standards on future cryptographic systems. Testimony to this is the quick move by WhatsApp to develop an end-to-end encryption scheme for their instant messaging application.

This paper extends the work proposed in [20], which proposes a neural cryptosystem for cloud-bound data. This work shows how cloud users can encrypt their confidential data before uploading it to the cloud. The cryptosystem proposes a one-time pad (OTP) in which the data to be encrypted must be of equal length to the encryption key. The study further proposes the use of a counter propagation neural network for key storage and revocation. However, the proposed system is not tested against existing encryption solutions to determine its efficiency. Hence, this paper adopts the techniques in [20] to generate encryption keys for DES, 3-DES and AES, based on chaos theory to have an objective analysis of the encryption systems.

In summary, various researchers have suggested several methods of protecting cloud-hosted data through encryption and key management. However, existing systems fall short when it comes to providing data confidentiality guarantees. Existing research suggests solutions requiring high processing power and large memory requirements. This becomes a problem when considering client-end security. Another issue with existing cryptosystems is their increasing reliance on third party KDCs. The idea of KDCs requires a lot of trust as the third-party entity can have access to the confidential data. Moreover, KDCs are often targeted by cybercriminals. Hence, new encryption schemes that provide data confidentiality guarantees and secure encryption key storage are needed. Therefore, this paper proposes a light-weight chaos-based encryption system. It also aims to strengthen existing

encryption schemes by producing encryption keys from chaotic random noise in the quest to have strong keys for DES, 3-DES and AES. The next section discusses the proposed model.

III. PROPOSED MODEL SOLUTION

This section introduces the proposed solution which aims to fill the gaps identified in the reviewed literature and provide confidentiality guarantees through a client-end encryption scheme. Encryption and key management is a big issue, especially in a multi-tenant and distributed environment like the cloud. The proposed model seeks to address the issue of data confidentiality through strong encryption. The proposed scheme is based on symmetric key encryption. This means that the same key is used to encrypt and decrypt data. Furthermore, the proposed scheme is based on evolutionary computing concepts. These concepts introduce a paradigm shift in terms of conventional approaches to encrypting data associated with the Kerckhoff-Shannon principle. The concepts adhere to static algorithms and dynamic encryption keys.

Moreover, evolutionary computing concepts explore how encryption algorithms and keys can quite literally be generated ‘on the fly’. This is done so that a user can be provided with, or, better still, individually generate a personalised encryption algorithm in addition to a personalised encryption key. To provide an extra layer of security, the model discussed below uses an evolutionary Eureqa system seeded with natural noise to create unlimited amounts of fitness functions, which will eventually be used to generate one-time pads (OTPs).

To meet the objectives and fill the gaps identified in the review of existing literature, the proposed cryptosystem has the following functional requirements.

A. Functional requirements

- Client-end: The system must be able to encrypt cloud user’s data before it could be uploaded on the cloud. The encryption keys and everything concerning the model should be done by the client. The CSP must never gain access to the encryption algorithm or keys.
- Light-weight: The system must be able to encrypt and decrypt data on the fly and without requiring a lot of computational resources. This is to enable our proposed solution to be suitable for devices with minimal computing resources like mobile devices.
- Secure key management – The system must be able to manage encryption keys securely and effectively. This also must be done on the client end.
- Self-destruction of keys – The system must be designed such that it can discard encryption keys once the encryption is complete.

Each of these requirements is taken into consideration in the design and implementation of the proposed model. The proposed model is presented by Fig.1 below which depicts the architecture of the proposed encryption and key management scheme.

Figure 1: Proposed model solution

The model describes the process of encrypting cloud-bound data on the client-end and how encryption keys are managed.

The process is initiated by generating random noise. The noise can be from any source. In this paper, the noise was sourced from [21]. The noise is then transmitted into the Eureka cloud-based system through a secure channel, using transport layer security (TLS). Eureka implements an exhaustive search which mimics the concepts of evolutionary computing to generate a non-linear fitness function that fits the input noise. The fitness function is then used to generate a symmetric key to encrypt cloud-bound data. The resultant key exhibits the random and chaotic properties of the input noise. Hence, the strength of the symmetric keys is derived from the chaotic and random nature of the input noise. Hence, we argue that the fitness function is the best approximation of the input noise. The next section outlines the process of generating encryption keys from the resultant fitness function.

B. Encryption key generation process

To generate random encryption keys, the fitness function is normalized using random floating-point numbers in the range [0,1]. This produces a set of random outputs. The outputs are randomly picked and converted into a binary stream. The minimum length of the binary stream is 56-bits. This is chosen based on the length of a DES key for close comparisons with existing cryptosystems. If the output bit stream is less than 56 bits, the process is repeated and the random binary outputs are concatenated to form the desired length (i.e. 56 bits). The key length depends on the encryption algorithm to be used i.e. DES, 3-DES, AES and Cryptor. DES and Cryptor use a 56-bit encryption key. However, Cryptor can use resizable encryption keys. This means Cryptor uses keys of variable length, compared to DES which uses 56 bits only. This conforms to having static algorithms with evolving key streams.

Hence, the strength of the encryption keys emanates from the random property of the floating-point numbers derived from the chaotic and random attributes of the input noise. It is on this premise, that the proposed system is believed to achieve strong encryption keys which are not reliant on the key length

but chaos and randomness. The following algorithm summarises the encryption process.

C. Key generation and encryption algorithm

Algorithm 1: Key generation and encryption

1. Generate random noise
2. Input random noise into the Eureka system
3. Obtain a fitness function
4. Generate random floating-point numbers between [0,1]
5. Normalize the fitness function with random floats
6. Convert random outputs to binary to generate random encryption keys
 - 6.1. Pick an encryption key at random
 - 6.2. Check length of key depending on the encryption algorithm to be used
7. Encrypt plaintext
8. Send ciphertext and key into the neural network
9. Neural network learns the key and ciphertext patterns
10. Neural network outputs ciphertext
11. Send ciphertext to the cloud for storage
12. Discard the encryption key

The key generation phase in the algorithm above is generic to all the encryption schemes discussed herein. Step 7 in the algorithm is unique to each scheme. For example, Cryptor implements the encryption through an exclusive or i.e. XOR operation. Thus, the encryption is based on a one-time pad implementation. Therefore, the length of the key and the plaintext must be equal in order to encrypt data successfully. Steps 8-10 describe how the ciphertext and the encryption key are processed by the neural network. The ciphertext is used as input into a counter propagation neural network (CPNN) together with the encryption key. The next section discusses the structure of a CPNN.

D. Encryption key generation process

A CPNN is a hybrid of other neural networks. It consists of a combination of a structure widely known as a competitive

network [22]. A CPNN is a variant of a neural network consisting of three layers: the input, Kohonen (i.e. hidden) and Grossberg (i.e. output) layers. The structure of a CPNN is depicted in the fig. 2 below:

Figure 2: Structure of a CPNN

There are two important aspects of a CPNN. These are supervised and unsupervised learning. The Grossberg layer uses supervised learning while the Kohonen layer uses unsupervised learning. Depending on the learning scheme used, the weights of the input vectors are automatically changed [23]. The inputs to the CPNN are the encryption key and the ciphertext, as a set of vectors, in binary form. Given a set of vector pairs $(X_1, Y_1), (X_2, Y_2), \dots, (X_m, Y_m)$, a CPNN is able to learn and associate an X vector given in the input layer with a Y vector. If there is a continuous function, f , relating X and Y vectors such that the following equation is satisfied:

$$y = f(x) \quad (1)$$

The CPNN is trained to learn patterns of the binary ciphertext and encryption key. Once the key has been learnt, it is then discarded to avoid getting compromised.

Decryption can only be done by the data owner. This is done in such a manner that the CSP or any unauthorized third-party entities cannot decrypt the data. This provides the user with absolute assurance of the confidentiality guarantees of their cloud-hosted data. Once the ciphertext has been downloaded from the cloud, it is sent into neural network to be processed. The neural network uses unsupervised machine learning to reconstruct the key, from the ciphertext patterns. Fig.2 below presents the decryption model.

The output of the neural network is compared with the target value set during the training phase by computing the Euclidean distances. If the target value matches the ciphertext at each instance, the corresponding encryption key (which was used as input during encryption) is produced. The key value is converted back to binary form. The plaintext is recovered by performing the reverse of the encryption process. The encryption key is discarded once the decryption process halts. The next section discusses the results.

IV. DISCUSSION OF RESULTS

The results presented herein compare Cryptor with DES, 3-DES, AES-128, AES-192 and AES-256. These cryptosystems were chosen because they are also symmetric and are widely used for data encryption. Hence, they have some similarities with Cryptor.

A cloud infrastructure was set-up to test the application and practicability of the proposed model solution on a live cloud infrastructure. We used OpenNebula 4.12.3 which comes with a kernel-based virtual machine (KVM) hypervisor. OpenNebula does not have an encryption module. Thus, the proposed system provides a contribution towards development of modern-day cryptography by being integrated into the cloud infrastructure easily to provide a client-end security service to cloud users. The encryption schemes were used to encrypt a text file of-167 bytes in size. Table 1 depicts the overall performance of the encryption schemes when encrypting the text file. It also shows the CPU and memory use in percentages.

TABLE I
OVERALL PERFORMANCE OF CRYPTOSYSTEMS

Attribute	Cryptosystems					
	Cryptor	DES	3DES	AES-128	AES-192	AES-256
Key size(bits)	≥ 56	64	192	128	192	256
File (bytes)	167	167	167	167	167	167
Enc time (ms)	126	12.4	13.4	87.9	165	149.6
Dec time (ms)	128.3	10	14	67.7	144	130.4
Memory (Mb)	8	4	4	6.3	11.1	15.3
CPU (%)	1.009	1.289	1.322	1.005	1.007	1.009

In terms of computing resources such as CPU and memory, Cryptor has better results compared to DES and 3-DES. The results mean that Cryptor is indeed a light-weight cryptosystem. It therefore meets the functional requirements. Thus, the cryptosystem can be deployed on computing devices with low memory and CPU specifications given that it is designed to be a client-end cryptosystem. Most client devices have low specifications. For example, mobile devices. Hence, Cryptor can be executed from them.

In terms of encryption and decryption times, Cryptor performed better than AES-192 and AES-256. These results show that the encryption scheme is indeed efficient and achieves its objective.

Fig. 3 depicts the encryption and decryption times, measured in milliseconds for all five encryption schemes.

Figure 3: Encryption vs Decryption times

Cryptor took 126 milliseconds to encrypt the text file. DES encrypted the text file in 12 milliseconds. 3-DES encrypted the text file in 13 milliseconds. AES-128 took 87 milliseconds, AES-192 took 160 milliseconds and AES-256 recorded 149 milliseconds to encrypt the same text file. In this regard, only

DES, 3-DES and AES-128 encrypted the text file faster than Cryptor. The former encrypts the text file with the least amount of time. Cryptor outperformed AES (192 and 256). These results were obtained after ten consecutive runs. On average, Cryptor performs comparatively better than the other two variants of AES (i.e. AES-192 and AES-256).

V. CONCLUSION AND FUTURE WORK

This paper presented a novel cryptographic scheme based on chaos and neural cryptography. The proposed scheme uses chaotic random noise to improve the strength of encryption keys. The strength of the encryption keys does not rely on the length of the key but the random and chaotic nature of the input noise. Several experiments were conducted to test different aspects of the solution implemented. Overall, it is concluded, based on the results, that chaos theory can be applied in cryptography to improve the strength of ciphers. The results show that Cryptor is a lightweight, strong client-end encryption scheme. Hence, Cryptor is a better encryption scheme in terms of encryption and decryption times. The chaos-based encryption keys can be used to improve the strength of existing cryptosystems such as DES, 3-DES and AES. Future perspectives include: experimenting on encrypting multimedia digital content, implementing the Cryptor system to have rounds of encryption to increase layers of security, and to test the proposed neural key store against various types of key attacks.

Napo Mosola has just completed his MSc in Computer Science, at the University of KwaZulu-Natal (UKZN), Westville, Durban, focusing on cryptography. He obtained a BSc and BSc (Hons) in Computer Science from the National University of Lesotho (NUL) and University of Johannesburg (UJ), respectively. He is currently a member of the Mathematics and Computer Science (MACS) department at NUL. His research interests include cybersecurity, artificial intelligence, machine learning, the Internet of Things (IoT) and cloud computing.

Moses Dlamini is a PhD candidate at the University of Pretoria. He is also a researcher in the DPSS unit at the CSIR, South Africa. He obtained his BSc in Mathematics and Computer Science, BSc(Hons) in Computer Science, MSc in Computer Science, from the University of Pretoria. His research interests include cloud computing, big data, cryptography and information security.
